Abstract

We present a new approach for indexing animated objects and efficiently answer queries over their position in time and space. In particular, we consider an animated movie as a *spatiotemporal* evolution. That is, a movie is viewed as an ordered sequence of frames, where each frame is a 2-dimensional space occupied by the objects that appear in that frame. The queries of interest are range queries of the form: "find the objects that were in area S between frames f_i and f_j", as well as nearest neighbor queries like: "find the q nearest objects to a given position between frames f_i and f_j". The straightforward approach to index such objects is to simply represent the frame sequence as another dimension and use a 3-dimensional access method (like an R-Tree or its variants) to index all objects. This is problematic since objects that appear through many consecutive frames are assigned long "lifetime" intervals. Long intervals are particularly difficult to cluster efficiently in a 3-dimensional index. Instead we propose to reduce the problem to a partial-persistence problem, that is, we use a 2-dimensional access method that is made partially persistent. We show that this approach leads to faster query time while still using space proportional to the total number of changes in the frame evolution. What differentiates this problem from traditional temporal indexing approaches is that objects are allowed to move and/or change their extent continuously between frames. We present novel methods to approximate such objects. We formulate the problem as an optimization problem for which we provide an optimal solution for the case where objects move linearly. Finally, we present an extensive experimental study of the proposed methods. While we concentrate on animated movies, our approach is general and can be applied to other spatiotemporal applications as well.

1 Introduction

We consider the problem of indexing objects in animated movies. In our setting, an animated movie corresponds to an ordered sequence of frames. In this sequence, each frame (or screen) is a 2-dimensional space that contains a collection of objects. As the movie proceeds, this collection of objects changes from one frame to the next (new objects are added, objects move, change in size, disappear, etc.) For the purposes of editing or assembling movie sequences, it is important to have efficient ways to access and replay all, or parts, of such movies. In particular we are interested in topological range queries of the form: "find all objects that appear in area S between frames f_i and f_j", and nearest neighbor queries like: "find the q objects that appear closest to a given position A during frames f_i and f_j". S and A are part of the 2-dimensional frame screen. For example the movie editor may want to find all the objects that are inside a given window region in a sequence of consecutive frames.

A conceptual view of a movie sequence appears in Figure 1. The areas along the x and y axes represent the 2-dimensional frame screen while the f axis corresponds to the frame sequence. Frame f_1 contains objects o_1 (which is a point) and o_2 (which is a region). At frame f_2, object o_3 is inserted while o_1 moves to a new position and o_2 shrinks. Object o_1 moves again at frame f_5; o_2 continues to shrink and disappears at frame f_5. The Figure also shows a simple query: "find all objects inside area S in frame f_3"; only object o_1 satisfies this query.

It should be noted that objects in movie sequences can be referred to at three different abstraction levels, namely: *raw, feature* and *semantic* levels [29][38][19][25]. At the raw abstraction level, an object is an aggregation of pixels from a frame. At this level, the interest is mainly in object comparisons which are performed pixel by pixel. At the next higher level, frames are characterized by image features like gray scale, luminance or color histogram. Objects are identified through frame regions that consist of homogeneous feature vectors. Usual queries at this level are similarity queries in a multidimensional feature space. At the highest level, semantic information about the objects and their relative positions in a frame has already been extracted and can thus be used to index these objects. Such semantic information leads to content-based queries, i.e., queries about the actual objects in a movie.

Most of the previous research on indexing images or movies has concentrated on the raw and feature levels and examines *similarity* based queries [15] [17] (for example, find two similar images). Our work is different in that (i) it deals with the semantic level, and, (ii) the queries are topological in nature (i.e., the relative position of objects in space and frame is of importance). To the best of our knowledge, the problem is novel. Very recently, [45] examines similar topological queries for multimedia applications but it addresses a special case (the "degenerate" case discussed below).

We propose to index an animated movie as a spatiotemporal evolution. That is, a movie is viewed as an ordered sequence of frames $f_i, i > 0$, where each frame is a 2-dimensional space occupied by the objects that appear in that frame. Time is discrete and corresponds to the sequence of frame numbers. In the rest we will use the terms time instant and frame number

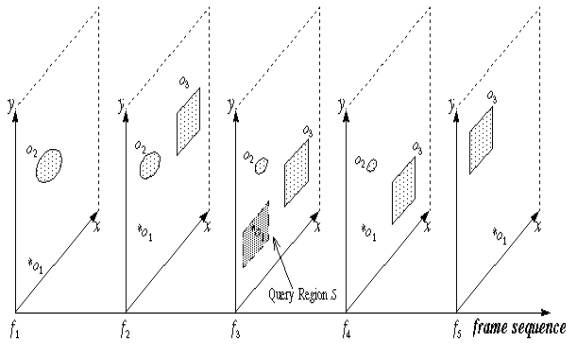

Figure 1: A conceptual view of a movie sequence.

interchangeably.

By considering an animated movie as a spatiotemporal evolution each object is assigned a record with a "lifetime" interval $[f_i, f_j)$ that corresponds to the frames where the object was added (insertion frame) and deleted (deletion frame) from the movie. We consider two types of evolutions, namely the *degenerate* case and the *general* case. In the degenerate case (Figure 2) objects are simply added or deleted from the movie. That is, during its lifetime, an object remains in the same position and retains the same 2-dimensional extent (region). This type of evolution is rather static. The only changes in the degenerate evolution are object insertions and deletions. Note that since a deletion is represented as a "logical" deletion (i.e., a deletion simply updates the lifetime interval of the deleted object's record), important for the design of the index are the number of objects indexed. That is, the number of insertions N. Since the history of an evolution is maintained, N represents the total number of records created and thus measures the space the index will use.

More interesting (and realistic) is the general case where objects are allowed to move and grow/shrink among frames during their lifetime (Figure 1). However, in the general case it is not obvious how position and extent changes can be quantified as object insertions. Consider for example an object that moves from position A in frame f_i to a new position C in the next frame f_{i+1}. The simplest way to represent such movement is to delete the object from position A in frame f_{i+1} and reinsert it in position C at the same frame. This creates two records for this object, one record storing position A and whose lifetime ends at f_{i+1} and one record with position C and lifetime starting at f_{i+1}. The object's lifetime has been "artificially" truncated into two records with consecutive and non-overlapping intervals. This approach is not efficient if objects alter positions/extents continuously through frames as it creates a large number of artificial insertions and thus it increases the index storage space.

A better way is to store the functions describing how objects move or vary their extents. This is particularly the case in animated movies where an object's frame evolution is represented by some function (see also [1]). Even though general functions can be used, for simplicity we assume an object can move or grow/shrink through a *linear* function of time. Then a new record is inserted only when the parameters describing an object's movement or

extent functions change. The new record will maintain the object's lifetime under the new movement/extent function. Then in the general case the number of insertions N corresponds to: (i) regular object insertions, and, (ii) insertions due to function parameter changes.

We distinguish between two different modes of operation. In the On-Line mode, when a new object is inserted at frame f_i, its deletion frame is not yet known, so its lifetime is initiated as $[f_i, now)$ where *now* is a variable representing the (ever increasing) current frame number. If this object gets deleted at a later frame f_j, its lifetime interval is updated to $[f_i, f_j)$. Instead, in the Off-Line mode, we know in advance for each object its insertion and deletion frames as well as its positions and extents in between. Obviously, in the Off-Line mode, the constructed index is expected to be more efficient since we have more information about the data. This paper concentrates on the Off-Line mode, since this is the case in animated movies. There are other spatiotemporal applications where the future of the evolution is unknown and the On-Line mode is more appropriate (for example storing the evolution of a collection of cars moving in the plane).

Using the spatiotemporal approach, one straightforward way to index animated objects is to consider time (the frame sequence) as another index dimension. Then each object can be stored as a 3-dimensional rectangle in a traditional spatial index (e.g. an R-Tree [16] or its variations [21, 35, 6]) where the "height" of the rectangle corresponds to the object's lifetime interval. The "base" of the rectangle corresponds to the largest 2-dimensional minimum bounding rectangle (MBR) that the object obtained during its lifetime. Since this approach uses an "of-the-self" spatial index, it is straightforward to implement. However, it does not take advantage of the specific properties of the time dimension. Objects remaining unchanged for many frames will have long lifetimes and thus, they will be stored as long rectangles. A long-lived rectangle determines the length of the frame range associated with the page in which it resides. This makes the clustering of objects into pages very challenging and leads to decreased query performance.

In an attempt to overcome the above problems with storing intervals, a variation of the R-Tree has been proposed, the Segment R-Tree (SR-Tree) [23]. The SR-Tree combines properties of the R-Tree and the Segment Tree, a binary tree data structure that stores line segments [34]. In the SR-Tree, intervals can be stored in both leaf and non-leaf nodes. An interval I is placed to the highest level node X of the tree such that I spans at least one of the intervals represented by X's child nodes. If I does not span X, spans at least one of its children but is not fully contained in X, then I is fragmented. Using this idea, long intervals will be placed in higher levels of the tree, thus the SR-Tree tends to decrease the overlapping in leaf nodes (in the regular R-Tree, a long interval stored in a leaf node will "elongate" the area of this node thus exacerbating the overlap problem). Interval fragmentation implies storing fragments of the same interval in many places.

In contrast, we propose to use a different approach in indexing animated objects which combines a spatial index (R-Tree) with the partially persistent methodology. A data structure is called *persistent* [14] if an update applied to it creates a new version of the data structure while the previous version is still retained and can be accessed. A data structure that does not

keep its past is called *ephemeral*. *Partial* persistence implies that all versions can be accessed but only the newest version can be modified.

Partial persistence fits nicely with the degenerate case of the problem we address. This is because in the degenerate case an update simply corresponds to object additions/deletions. Methods to make a disk based structure (in particular a B-tree) partially persistent have appeared in the area of temporal databases [20, 5, 26, 46, 24]. [24] presents the Bitemporal R-Tree which is a partially-persistent R-Tree used to index bitemporal objects. This partially-persistent R-Tree can be easily extended to index the degenerate case of animated objects.

However the general case where objects change continuously is different. One approach is to represent an object's movement or extent change by the largest 2-dimensional MBR that the object obtained during its evolution (*maxMBR*). For example, in figure 1 the largest MBR in the evolution of object o_2 occurs at frame f_1. Then the evolution of o_2 can be represented by the insertion of this MBR at frame f_1 and the deletion of the *same* MBR at frame f_4. While this representation creates only one record, it creates a large empty space for the partially persistent methodology. Even though object o_2 reduces its extent as frames advance, it is still represented by the larger MBR. Empty space in R-Trees is known to deteriorate query time.

To reduce empty space we propose to introduce a limited number of artificial updates. An artificial update deletes an existing object and reinserts it, thus adding an extra record. In order to maintain the index storage space linear to the number of real evolution insertions N, we limit the number of artificial updates to be a fraction of N. To apply the partially persistent methodology one must first decide: (i) which objects should be artificially updated and, (ii) on what frames the artificial updates are created. We formulate these questions as an optimization problem for which we provide a greedy algorithm that optimally finds the artificial updates for the case when objects move with linear functions. The algorithm is based on a special *monotonicity* property that holds for linear changes. This property holds also when objects change one of their (two) extent dimensions linearly. If both extent dimensions change, the algorithm does not provide the optimal solution, however it serves as a good heuristic that performs very well in practice.

We compare the Partial Persistent R-Tree with the SR-Tree and a standard implementation of the 3D R-Tree. Both selection and nearest neighbor queries are examined. Our experimental results show that the Partial Persistent R-Tree consistently outperforms both the SR-Tree and the conventional 3D R-Tree for a number of diverse query workloads at the expense of additional disk space. However, the space overhead required by our partial persistent implementations remains linear to the number of objects indexed.

Section 2 provides background on the partially persistent R-Tree and the degenerate case. Section 3 discusses the general case of animated objects as well as the greedy algorithm. Section 4 contains experimental results. Section 5 presents related work while 6 concludes the paper and presents future research work.

2 Preliminaries

For the Off-Line problem we measure the performance of an index using two costs: the query time and the storage space. Given the large sizes of animated movies we are interested in disk based solutions, i.e., the data is large and thus disk resident. Hence the indexing scheme should be designed so as to minimize the number of page transfers (I/O's) between the disk and main memory needed to answer a query while keeping the index storage requirements small. There are two basic parameters that affect performance: the total number N of (real) updates in the frame evolution and, B, the page size in records. We assume that one I/O transfers one page. Parameter N corresponds to the "minimal" amount of information needed to store the frame evolution. Ideally, we would like our index solutions to use space that is linear to the number of updates, i.e., $O(\frac{N}{B})$ disk pages [18]. Note that for the On-Line problem an additional cost measure is the index update time (the time to process an update). This is not critical in the Off-Line mode since the whole set of updates is known in advance and the index is built once.

To further exemplify the above costs, consider two obvious but inefficient ways to address topological queries about animated movies. The first is to store in the database snapshots of all movie frames. This "snapshot" approach provides fast access to the frames of interest, but extra work is needed to locate the objects in the query area S. The main disadvantage however is the high storage space redundancy. Many objects that do not change between frames will be stored several times. (At worst, the space can become quadratic to the number of updates in the frame sequence, i.e., $O(\frac{N^2}{B})$).

The second straightforward approach is to store the changes between frames in a "log". This approach uses minimal space $O(\frac{N}{B})$, but the query time is rather large as the frame of interest has to be reconstructed starting from the beginning of the log (at worst the whole log must be read resulting to $O(\frac{N}{B})$ query time). An intermediate approach is to store a number of frame snapshots and the sequences of changes between successive snapshots (similar idea as in MPEG). However, this approach has the following disadvantages: (i) it is not obvious how often to keep snapshots (frequent snapshots increase storage space, fewer snapshots increase query time), (ii) locating the objects in the query area S still requires extra effort that affects the query response time.

We proceed first with a discussion of the degenerate case. We then show how a Partially Persistent R-Tree can be extended to efficiently index this case.

2.1 Degenerate Case

In the degenerate case, an object is inserted at the first frame it appears on the 2-dimensional movie screen and remains as is until the frame it is deleted (disappears from the screen). A solution for this kind of spatiotemporal evolution has been proposed in [45], that utilizes a 3-dimensional R-Tree. The time dimension is considered as another dimension along with the spatial ones, and an object is represented by its 3-dimensional MBR. Figure 2 shows the MBRs of four objects in a degenerate evolution. As discussed in the introduction, with this

approach objects that remain unchanged over many frames will be stored as records with long lifetimes. The R-Tree will attempt to store these records as long rectangles (like object o_3 in Figure 2). causing a lot of overlapping between the nodes of the R-Tree. However, large overlapping decreases the R-Tree query performance.

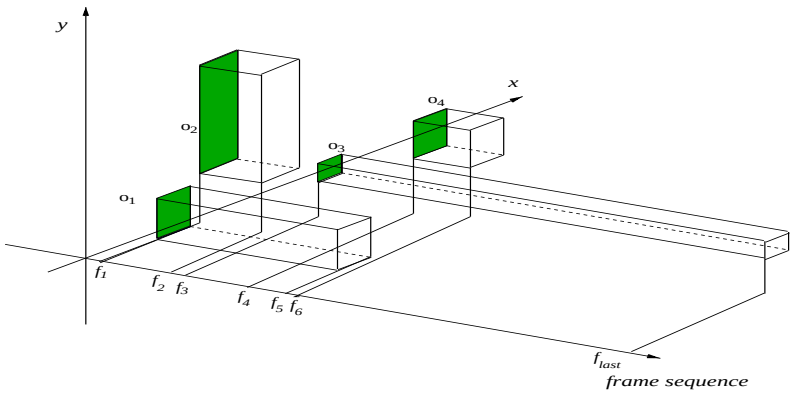

Figure 2: A degenerate spatiotemporal evolution of four objects.

The SR-Tree has been proposed as a remedy for storing intervals. Overlapping is decreased by placing long intervals in higher nodes of the structure. However if large numbers of spanning records or fragments of spanning records are stored high up in the tree may decrease the fan-out of the index as there is less room for pointers to children. [23] suggests to vary the size of the nodes in the tree, making higher-up nodes larger. "Varying the size" of a node means that several pages are used for one node. This adds some page accesses to the search cost.

As with the R-tree, if an interval is inserted at a leaf (because it did not span anything) the boundaries of the MBR covered by the leaf node in which it is placed may be expanded. Expansions may be needed on the MBRs of all nodes on the path to the leaf which contains the new record. This may change the spanning relationships since records may no longer span children which have been expanded. Such records are reinserted in the tree, possibly being demoted to occupants of nodes they previously spanned. Splitting nodes may also cause changes in spanning relationships as they make children smaller -former occupants of a node may be promoted to spanning records in the parent. Because of fragmentation, the worst case space requirements for an SR-Tree is $O((N/B)log_B(N/B))$ [33]. However, this is a pathological scenario that rarely happens in practice. To improve performance, [23] have also proposed the use of a Skeleton SR-Tree, which is an SR-Tree which pre-partitions the entire domain into some number of regions. This pre-partition is based on some initial assumption on the distribution of data and the number of intervals to be inserted. Then the Skeleton SR-Tree is populated with data.

A better approach is to use partial persistence. Considering the degenerate evolution of figure 2, assume that the objects in frame f_1 are indexed by a 2-dimensional R-Tree. As the frame number advances, this 2D R-Tree evolves, by applying on it the updates (object additions/deletions) as they occur in the appropriate frames. Storing this 2D R-Tree evolution corresponds to making a 2D R-Tree partially persistent.

By "viewing" a degenerate evolution as a partial persistence problem, we obtain a double advantage. First we disassociate the indexing requirements within a frame from the frame sequence. More specifically, indexing within a frame is provided from the properties of the ephemeral 2D R-Tree while the frame evolution support is achieved by making this tree partially persistent. Second, partial persistence avoids the long 3-dimensional rectangles and thus the extensive overlapping due to long lifetimes. Moreover, the partially persistent R-Tree uses storage space that is linear to the number of updates in the degenerate frame evolution.

2.2 Partially-Persistent R-Tree

To illustrate the partial persistence methodology we present how a 2D R-Tree is made partially persistent. Note that the methodology applies to other spatial indexes; we use a 2D R-Tree for simplicity.

The R-Tree [16] is a hierarchical, height-balanced index. It is a generalization of the B-tree for multidimensional spaces. Multidimensional objects are represented by a conservative approximation, usually their MBR. This approximation may introduce empty or dead space, which is the part of the MBR that is not covered by the object. The R-Tree consists of directory and leaf (data) nodes, each one corresponding to one disk page. Directory nodes contain index records of the form $(container, ptr)$ where ptr is a pointer to a node in the next level of the tree and $container$ is the MBR of all the records in the descendent node. Leaf nodes contain data records of the form $(container, oid)$ where oid is the object-identifier of the real object and $container$ is its MBR. All the nodes except the root must have at least m records (usually $m = B/2$). Thus the height of the tree is at most $log_m n$ where n is the total number of objects. Searching in the R-Tree is similar to the B-tree. At each directory node all records are tested against the query and then all child nodes that satisfy the query are visited. However, a drastic difference from the B-tree is that the MBRs in a R-Tree node are allowed to overlap. As a result, when answering a query, multiple paths may be followed, although some of these paths may not contribute to the answer. At worst all leaf nodes may be visited, however in practice R-Trees have been shown to work much faster.

[24] presents a partially persistent R-Tree (called the Bitemporal R-Tree) following an approach similar to [5] (which shows how to make a B-tree partially persistent). In temporal applications it is assumed that updates arrive in order. Hence we assume that all updates in the frame evolution are provided in a sequence ordered by frame id (the "update sequence"). For simplicity of exposition, assume at most one update per frame (in practice many updates happen per frame).

The partially-persistent R-Tree (PPR-Tree) records the evolution of an ephemeral R-Tree on which the above update sequence is applied. However, it does not store snapshots of all the versions of the ephemeral R-Tree. Instead it records the evolution updates efficiently so that the storage space remains linear, while still providing fast query time. The PPR-Tree is actually a directed acyclic graph of nodes (each node is again corresponding to a disk page). Moreover, it has a number of root nodes, where each root is responsible for recording a subsequent part of the ephemeral R-Tree's evolution. Data records in the PPR-

Tree leaf nodes maintain the frame evolution of the ephemeral R-Tree data objects. Each data record is thus extended to include the two lifetime fields: *insertion-frame* and *deletion-frame*. Similarly, index records in the directory nodes of the PPR-Tree maintain the evolution of the corresponding index records of the ephemeral R-Tree and are also augmented with insertion-frame and deletion-frame fields.

An index or data record is called *alive* for all frames during its lifetime interval. A leaf or a directory node is called *alive* if it has not been *split*. With the exception of root nodes, for all frame numbers that a node is alive it must have at least D alive records ($D < B$). This requirement enables clustering the objects that are alive at a given frame number in a small number of nodes (pages), which in turn will minimize the query I/O. The PPR-Tree is created incrementally following the update sequence. Consider an update (insertion or deletion) at frame f_i. To process this update the PPR-Tree is searched to locate the target leaf node where the update must be applied. This step is carried out by taking into account the lifetime intervals of the index and the data records visited. This implies that the search follows records that are alive at frame f_i. After locating the target leaf node, an insertion update adds a data record with an interval $[f_i, now)$ to the target leaf node. Instead, a deletion update will update the deletion-frame of a data record from now to f_i.

An update leads to a *structural* change if at least one new node is created. *Non-structural* are those updates which are handled within an existing node. An insertion update triggers a structural change if the target leaf node already has B records. A deletion update triggers a structural change if the resulting node ends up having less than D alive records as a result of the deletion. The former structural change is a *node overflow*; the latter is a *weak version underflow* [5]. Node overflow and weak version underflow need special handling: a *split* is performed on the target leaf node. This is reminiscent of the time-split proposal [26] and the page copying concept proposed in [43]. The split on a node x at frame f, is performed by copying to a new node y the records alive in node x at f. Node x is considered *dead* after frame f. (We can assume that the deletion-frame field of all x's alive records is changed to f even though this is not needed in practice). Then the resulting new node has to be incorporated in the structure (for details we refer to [24, 46, 5]).

Answering a range query about region S and frame f has two parts. First, the root alive at f is found. This part is conceptually equivalent to accessing the root of ephemeral R-Tree which indexes frame f. Second, the objects intersecting S are found by searching this tree in a top-down fashion as in a regular R-Tree. The lifetime interval of every record traversed should contain the frame f, while the record's MBR should intersect the region S. Answering a query that specifies a frame interval $[f, f')$ is similar. First all roots with lifetime interval intersecting the frame range are found and so on. Since the PPR-Tree is a graph, some nodes are accessible by multiple roots. Re-accessing nodes can be avoided by keeping a list of accessed nodes.

To answer nearest neighbor queries we use the algorithm proposed in [30] and later refined in [10]. The query consists of a point or object and a frame sequence. The answer contains the q nearest objects that are closest to the query object during the specified frame sequence. The

algorithm proposed in [30] can be used directly; the only difference is on the way distances are computed. All objects that are not alive during the query frame sequence have infinite distance to the query object. On the other hand for the objects that have lifetimes intersecting the query frame sequence, the distance is computed using their extent dimensions. The algorithm visits first the root of the tree and then traverses the tree in a top-down fashion. At each node, a list of the subtrees is kept, ordered by the minimum distance of each subtree to the query object. The subtrees are then visited in sorted order. A subtree is pruned from the search if the minimum distance of this subtree is larger than the distance of the $q-th$ nearest object found so far. The same algorithm is used with the PPR-Tree, after the root of the corresponding ephemeral R-tree is found.

3 General Case

The problem in the general case, is how to represent objects that continuously change positions and/or extent over time. Objects are still represented by MBRs but an efficient solution should minimize the empty space introduced by the MBR representation. To achieve that we introduce artificial deletions and re-insertions of objects. We proceed with some definitions.

Definition 1 *Consider a 2-dimensional spatial object o that moves and/or changes its extent during its lifetime interval L. This evolution creates a spatiotemporal object O^L which is the 3-dimensional volume occupied by o during it's lifetime L.*

In the rest we use capital letters to represent spatiotemporal objects; we sometimes drop the lifetime exponent to simplify the notation.

Definition 2 *Let G be a set of spatiotemporal objects. We define the function* **Empty:** $G \rightarrow R$ *that takes as input a spatiotemporal object and returns the empty space that is introduced by approximating the spatiotemporal object by a 3-dimensional MBR.*

Figure 3 shows the movement of object o_1 from frame f_1 to frame f_5. The corresponding spatiotemporal object is the shaded volume; the empty space is the volume that is contained inside the 3-dimensional MBR and is not shaded.

Next we define the (artificial) split operation. Consider the spatiotemporal object created by the evolution of object o from frame f_i to frame f_j. A split operation at frame f_s, where $f_i < f_s < f_j$, artificially deletes object o at frame f_s and reinserts it at the same frame with the same extent at the same position. As a result the original spatiotemporal object $O^{[f_i,f_s)}$ is replaced by two new spatiotemporal objects, namely $O^{[f_i,f_s)}$ and $O^{[f_s,f_j)}$. By adding two new spatiotemporal objects instead of the original one, the overall MBR empty space is expected to decrease since the original evolution is represented using more details.

Figure 4 shows the result of a split operation performed on a frame f_s on the object evolution of Figure 3. The view from the $x-axis$ is depicted (i.e., the spatial object is simply an interval that moved along the $y-axis$ from frame f_1 to frame f_5). The gain in empty space

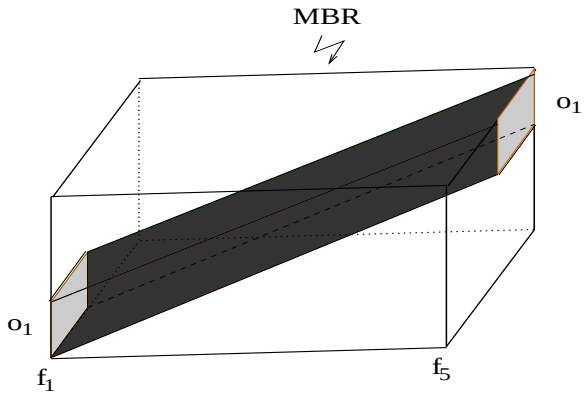

Figure 3: *A spatiotemporal object.*

is equal to $E_1 + E_2$. For the partially persistence approach, the above split is seen as having on object with interval y_1 with lifetime $[f_1, f_s)$ and object y_2 with lifetime $[f_s, f_5)$. Without the artificial split, we had an object y_{tot} with lifetime $[f_1, f_5)$. Using the split operation we can decrease the empty space, and consequently the possibility of overlapping among the nodes in the ephemeral R-Tree. Thus the query performance of the index is improved with the expense of course of using more space, since every time we perform a split, we increase the number of the indexed objects by one.

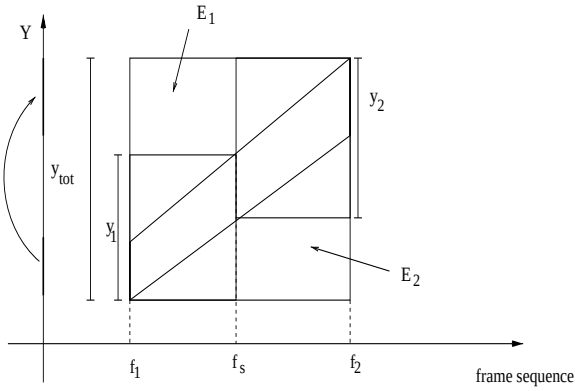

Figure 4: A split operation of an 1-dimensional object (interval) that moved continuously from frame f_1 to frame f_5.

The more general split operation allows a spatiotemporal object to be split many times.

Definition 3 *Consider again a spatiotemporal object* $O^{[f_i,f_j)}$. *Then the* **Split-k**(O) *operation partitions* $O^{[f_i,f_j)}$ *into* $k+1$ *spatiotemporal objects using* sp_l *splitting points, where* $f_i \leq sp_l \leq f_j, l = 1, ..., k$.

Since we assume that objects move with a linear motion over time, the best choice for k splitting points over a given spatiotemporal object (so as to minimize the empty space) is to take equidistant splits during the lifetime of the spatiotemporal object. Note that this is

true only for objects that move linearly (while retaining the same extent). It is also true for objects that change one of their extent dimensions linearly. However, it is not the optimal choice for objects that change both their extent dimensions. Although, there are ways to compute the best splitting points even in that scenario, these methods are computationally expensive. Therefore, in the rest we concentrate on linearly moving objects (i.e., no extent change) for which we will provide an optimal solution. Our solution can then be used as a good heuristic for the optimal choice of splits even for objects that change both extent dimensions linearly.

Consider now the problem of choosing the best splits that decrease the empty space over a set of (linearly moving) spatiotemporal objects. Clearly, as the number of splits increases the more accurate representation of the spatiotemporal objects is achieved and thus the empty space is reduced. On the one extreme is the case when splitting occurs for every spatiotemporal object. However, this creates high space overhead. A more realistic assumption is to put an upper limit on the number of splits. Then the challenge is to find which spatiotemporal objects to split and where to split them. More formally we consider the following problem, also termed the Minimization of Empty Space (MES) problem:

> **Problem Statement.** Given a set of spatiotemporal objects G and an upper limit on the number of splits k, find the optimal way to apply these splits so as to minimize the empty space.

The gain function below measures the gain in empty space after k splits.

Definition 4 *Let G be a set of spatiotemporal objects. Function* **gain:** $G \times \mathcal{N} \rightarrow \mathcal{R}$, *takes as input a spatiotemporal object O and an integer k and returns the following real value:*

$$gain(O,k) = Empty(O) - \sum_{1 \leq i \leq k+1} Empty(O_i)$$

where O_i are the objects that generated after applying the operation split-k(O).

For example, in the 1-dimensional case that is shown in Figure 4, we have $gain(O,1) = E_1 + E_2$. Next, we show that a special *monotonicity* property holds when objects move linearly over time. This property is used to prove the correctness of our splitting algorithm.

Lemma 1 *Let O is a spatiotemporal object created by a linear movement. Then for any i, j, with $i < j$:*

$$gain(O,i) - gain(O,i-1) \geq gain(O,j) - gain(O,j-1)$$

Proof. The position change is described by an equation of the form: $f(\bar{t}) = \alpha\bar{t} + \beta$. We initially provide formulas for the gain function and then show that the monotonicity property holds. Consider first the case where objects move or change their extent linearly on a 1-dimensional environment. An example is an interval that moves linearly over time over a

line. The gain obtained by splitting k times such a spatiotemporal object O is given by the equation:

$$gain(O,k) = \frac{k}{k+1} Empty(O)$$

where $Empty(O)$ is the empty space introduced by approximating the original spatiotemporal object with an MBR.

Figure 5 depicts an 1-dimensional object O that is split one and two times. With one split, the best split position is at the middle of the horizontal side of the original spatiotemporal object. The gain in empty space is $gain(O,1) = \frac{1}{2}E_1 + \frac{1}{2}E_2 = \frac{1}{2}Empty(O)$. With two splits, the best split positions are in the first third and the second third of the horizontal side. Now $gain(O,2) = \frac{2}{3}Empty(O)$. (Note that the above equation holds also for 1-dimensional objects that linearly change extent, or move and change extent.)

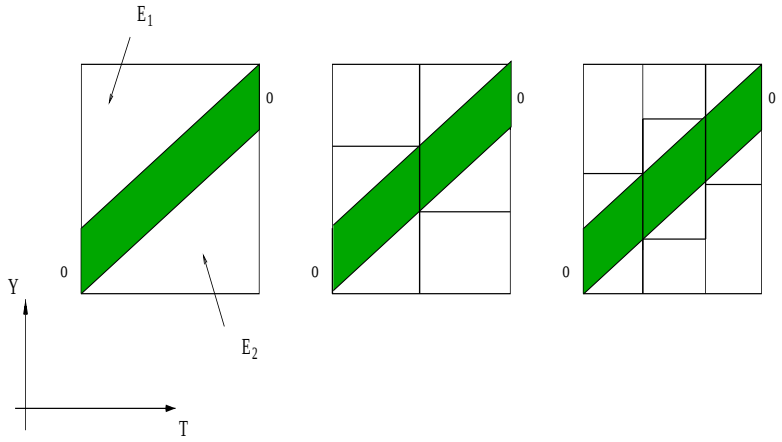

Figure 5: A 1-dimensional moving object with one and two splits.

The gain formula for a 2-dimensional space depends on whether the object has extent. For the case of a point moving linearly, the gain obtained after k splits is:

$$gain(O,k) = \frac{(k+1)^2 - 1}{(k+1)^2} Empty(O)$$

For example, assume that the moving point has initial position (x_1, y_1, t_1) and final position (x_2, y_2, t_2), where $x_1 \neq x_2, y_1 \neq y_2$ and $t_1 \neq t_2$. Then the MBR has volume $V = abc = (x_2 - x_1)(y_2 - y_1)(t_2 - t_1)$ which is equal to the empty space, since the moving point does not have extent (see Figure 6). After k splits, we get $k+1$ spatiotemporal objects, that approximated with $k+1$ MBRs. Since we split in equidistant points, each rectangle (MBR) has sides $\frac{a}{k+1}$, $\frac{b}{k+1}$ and $\frac{c}{k+1}$. The total volume for these rectangles is:

$$V_{splits} = (k+1)\frac{a}{k+1}\frac{b}{k+1}\frac{c}{k+1}$$

and finally the gain in empty space from the k splits is:

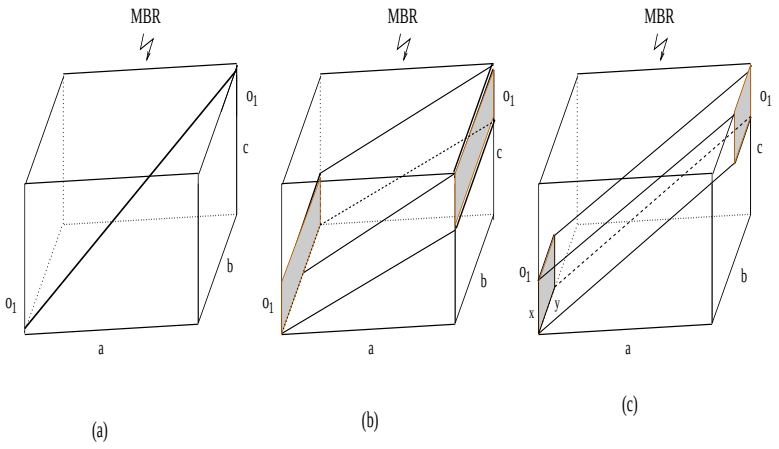

Figure 6: Three cases for 2-dimensional moving objects, (a) point, (b) moving rectangle with the same starting and ending x-coordinates and (c) moving rectangle with different starting and ending x and y coordinates.

$$gain(O,k) = V - V_{splits} = \frac{(k+1)^2 - 1}{(k+1)^2} abc$$

and this is equal to the previous equation.

An object with extent is represented by its 2-dimensional MBR. Hence consider a rectangle object that moved from some initial position to a final one. The position of this rectangle is defined by the position of its center. If the initial and final positions have one common coordinate (x or y), the gain is described by a similar formula as in the 1-dimensional space. Note however that the empty space in the 1-dimensional case refers to an area while in two dimensions it refers to volume.

If the initial and final positions have different x and y coordinates (see Figure 6), the gain formula involves also the spatial extent of the object. Using the same arguments as for point objects it can be shown that:

$$gain(O,k) = \frac{(k+1)^2 - 1}{(k+1)^2} abc - \frac{k}{(k+1)^2}(aby + acx) - \frac{k^2}{(k+1)^2} axy$$

Using the above gain functions it is easy to prove that $f(k) = gain(O,k) - gain(O,k-1)$ for each O and $k \geq 1$ is a monotonically decreasing function of k, i.e.,

$$\frac{df(k)}{dk} \leq 0.$$

□

It should be noted that the above property does not hold for spatiotemporal objects created by non-linear movement functions. For example, Figure 7, shows the case of a 1-dimensional moving object, where two splits provide a gain (shown as a shaded area) that is larger than the gain with one split. Similar examples exist for 2-dimensional objects.

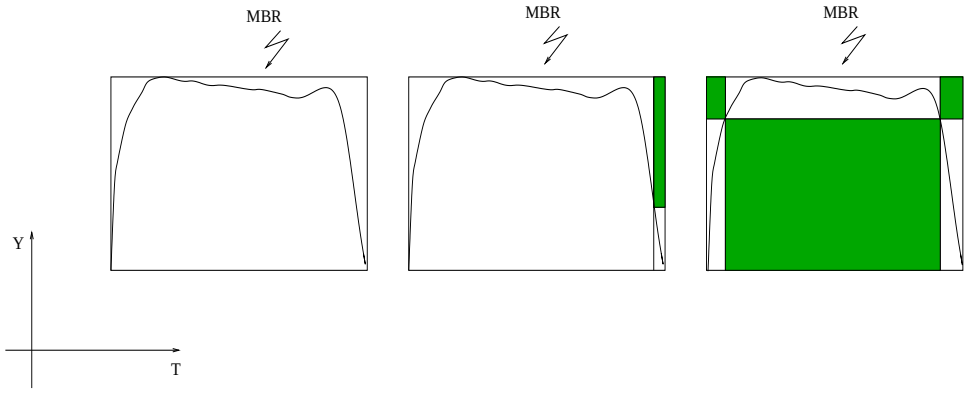

Figure 7: The spatiotemporal object created by a 1-dimensional moving point and the gain after one and two splits.

The monotonicity property simply states that the more we split a spatiotemporal object the less gain we get, in terms of empty space. So the first few splits will give high gain in empty space, but after some point the gain in empty space will be small.

As presented the MES problem minimizes the empty space in the 3-dimensional space. However by minimizing this empty space, we also minimize the total empty space for the PPR-Tree. Empty space in the PPR-Tree is introduced due to approximating a moving object with the 2-dimensional rectangle that encloses the object for all time instants during its lifetime (maxMBR). Introducing the artificial splits enables the PPR-Tree to better approximate an object's evolution. Hence its query performance will improve.

On the other hand, the 3D R-Tree is not expected to be significantly affected by the splits. To justify this, we use the results presented in [40]. In this paper the authors give an analytical model to approximate the number of pages accessed in an R-Tree, given a range query. This number is proportional to the number of indexed objects and also proportional to the density of the dataset. In particular, they give the following equation for the number of data pages accessed for a 3-dimensional dataset of m hyper-rectangles.

$$DA(q) = \frac{m}{f}((\frac{D_1 f}{m})^{1/3} + q_x)((\frac{D_1 f}{m})^{1/3} + q_y)((\frac{D_1 f}{m})^{1/3} + q_z)$$

and

$$D_1 = (1 + \frac{D^{1/3} - 1}{f^{1/3}})^3$$

where f is the capacity of each node in the tree, and $q = (q_x, q_y, q_z)$ is a range query. Also D is the density of the data objects and is defined as the average number of objects that contain a given point in the data space. These equations show that split operations will not necessarily decrease the query overhead, since a split operation decreases the density of the dataset (D), but at the same time increases the number of indexed objects (m).

3.1 An Optimal Greedy Algorithm

In this subsection we introduce an optimal greedy algorithm for the MES problem with linearly moving objects. We also discuss possible implementation methods of the algorithm.

Figure 8 describes the algorithm. We use the notation Q_i to denote a vector of size N (the number of spatiotemporal objects created by the linear movements). Each position in this vector corresponds to an object and stores the number of splits for the associated object in the optimal solution. We initiate this vector with the N dimensional zero vector $\bar{0} = (0, ..., 0)$. Then we find the optimal solutions for one, two, ..., up to K splits. The basic idea is that the optimal solution for i splits, can be derived from the solution for $i-1$ splits, if we choose to split one object one more time. The vector e_j has zero values to all position except the position j whose value is one (1). Thus we choose from all possible objects, the one that gives the higher gain in empty space.

A naive implementation of this algorithm will have complexity $O(KN)$ operations in main memory. Note that to find the object that gives the optimal solution with one more split, one needs to check only the objects that give the maximum gain. Hence the objects can be stored in a priority queue, sorted by the gain obtained if each object is split once more. Then at each step the object that gives the highest gain is chosen. Suppose that at some point object o_j is chosen to be split and assume this object has already l splits. Then the algorithm computes the difference between the gain obtained by splitting the object using $l+1$ splits ($gain(o_j, l+1)$) and its current gain. That is, the object is inserted in the queue with value $gain(o_j, l+1) - gain(o_j, l)$.

Given a set G of N (linear) spatiotemporal objects and a value for the input parameter K (an upper limit to the number of splits),

1. Set $Q_0 = \bar{0}$. Compute for each object the gain obtained with one split and insert it to a priority queue.
2. Repeat for $i = 1$ to K
   (a) Get the top element of the queue, delete this object and let this be the object j.
   (b) Set $Q_i = Q_{i-1} + e_j$
   (c) Compute the difference in gain obtained if object j is split one more time and insert the object into the queue using this value.

Figure 8: The Optimal GREEDY algorithm

Next we state and prove the following theorem:

Theorem 1 *There is an algorithm that solves the MES problem for linearly moving objects optimally. This algorithm can be implemented in main memory with complexity* $O(N +$

$KlogN$) and in external memory with $O(\frac{N}{B}log_{\frac{M}{B}}\frac{N}{B})$ I/O's, where M is the size of the main memory in records.

Proof.

First we prove that indeed the GREEDY algorithm finds the optimal solution. Let Q_k be the vector that stores the optimal solution for the MES problem of N objects with k splits. That is, the solution that minimizes the empty space by using k splits. We then derive the solution for $k+1$ splits.

Let $Q_k = \{k_1, k_2, ..., k_N\}$, where $k_i, i = 1, .., N$ are the number of splits for each object. Thus the first object has to be split k_1 times, the second one k_2 and so on. Also we have that $\sum_{i=1}^{N} k_i = k$. We claim that the optimal solution for $k+1$ splits has the form $Q_{k+1} = \{k_1, ..., k_i + 1, ..., k_N\}$ for some $i \in \{1, ..., N\}$.

Let assume that this is not true and that the optimal solution for $k+1$ splits has the form: $Q_{k+1}\prime = \{k_1, ..., k_i + 2, ..., k_j - 1..., k_N\}$ for some i and j.

Since Q_k is the optimal solution for k splits, we have that:

$$gain(o_i, k_i + 1) + gain(o_j, k_j - 1) \leq gain(o_i, k_i) + gain(o_j, k_j)$$

$$\Rightarrow gain(o_i, k_i + 1) - gain(o_i, k_i) \leq gain(o_j, k_j) - gain(o_j, k_j - 1)$$

Also by Lemma 1 it holds that:

$$gain(o_i, k_i + 2) - gain(o_i, k_i + 1) \leq gain(o_i, k_i + 1) - gain(o_i, k_i)$$

Therefore,

$$gain(o_i, k_i + 2) - gain(o_i, k_i + 1) \leq gain(o_j, k_j) - gain(o_j, k_j - 1)$$

$$\Rightarrow gain(o_i, k_i + 2) + gain(o_j, k_j - 1) \leq gain(o_i, k_i + 1) + gain(o_j, k_j)$$

The last inequality implies that Q_{k+1} is an optimal solution since we can split object o_i $k+1$ times and object o_j k_j times and have a better solution (or at least the same) with a solution of the form $Q_{k+1}\prime$. The same can be shown for any other solution with $k+1$ splits.

Thus, the optimal solution for $k+1$ splits can be derived by the optimal solution with k splits and the algorithm in Figure 8 does exactly this.

To implement the greedy algorithm efficiently we need to implement a priority queue. For this queue we use a heap. The creation time of this heap is $O(N)$ for N objects [11]. Then each insertion or deletion takes $O(logN)$ operations and the running time of the algorithm is $O(N + KlogN)$. Under the assumption that $K = o(N)$, the running time of the algorithm becomes $O(NlogN)$.

Since for the applications we have in mind the number of spatiotemporal objects is large and cannot be kept in main memory, an external memory priority queue is needed. We propose using an implementation of an external memory priority queue that is based on the buffer tree [3]. The basic idea is to perform operations (insertions and deletions) off-line in

such a way that the amortized complexity of each operation is $O(\frac{1}{B} log_{\frac{M}{B}} \frac{N}{B})$ [4]. As a result the running time of the algorithm in external memory becomes $O(\frac{N}{B} log_{\frac{M}{B}} \frac{N}{B})$ I/O's. □

Note that the above proof works similarly for the case where objects do not move but change only one of their extent attributes linearly. As mentioned earlier it works as an approximation otherwise.

4 Performance Evaluation

We first describe the datasets and outline the workloads used in our experimental evaluation. Then, subsection 4.2 discusses the performance characteristics of various implementations (tuning) of the PPR-Trees that we have developed. Finally, we present experimental results for both types of object evolution namely, the degenerate (subsection 4.3) and the general (subsection 4.4) cases.

4.1 Experimental Setup

For all methods the page size was set to 1 kbytes and the maximum number of records per page was equal to 50 (B=50). For the insertion and deletion operations a buffer of 10 pages was used with a LRU replacement policy. In all methods, during the query phase the buffer was invalidated before a new query is executed (so that strengths and weaknesses of the various implementations are revealed). For the 3D R-Tree method, we used an implementation of the R*-tree [6]. We implemented the Skeleton SR-Tree based on the description in [23]. In our implementation we allowed index nodes to have larger pages (starting from the leaf nodes the page size doubles as the level reaches the root). At a given index page, one third is allocated to storing spanning segments while the rest is for index records. Overflow segments still appeared in higher level nodes; such segments were stored in additional pages. However, the reported query times for the Skeleton SR-Tree do not include accessing these overflow pages (i.e., the reported SR-Tree query times are underestimates of the actual ones).

We generated various spatiotemporal datasets to compare the performance of the different methods. The datasets for the degenerate case were similar to the spatiotemporal datasets described in [45]. Objects in a given frame were approximated by their 2-dimensional MBRs and the size of the frame was 1.0×1.0 (unit square). Moreover, 70% of the objects were small rectangles with small lifetimes. The length of each rectangle in the x and y axes was uniformly chosen from the interval (0, 0.04] and the centers of the rectangles were uniformly distributed in the unit square. The lifetime of each object followed a Poisson distribution with mean value equal to 50. Another 15% of the objects were large rectangles with small lifetimes. Here the length of each rectangle in spatial dimensions was uniformly chosen from (0, 0.6] and the lifetimes were the same as above. The remaining 15% objects were small rectangles with large lifetimes. The lifetimes for these objects were uniformly chosen between 250 and 500 frames. For each object a number of lifetimes between 0 and 10000 was generated, and the number of frames between subsequent lifetimes had the same characteristics as the lifetimes.

We generated five different datasets with objects per frame ranging from 250 to 2500. We call this type of datasets DG (degenerate).

For the general case we created two different types of datasets. First we had a collection of datasets containing only moving rectangles (the MV dataset). Each rectangle starts at a specific position and moves with a linear motion to its final position. Each set had one-third of "slowly" moving rectangles whose sides were uniformly chosen in $(0, 0.02]$, and speeds between 0 and 0.001. Another third had sides in $(0, 0.01]$ and speeds between 0 and 0.006 and finally "fast" objects with the same side lengths and speeds between 0 and 0.01. The rectangles retain their size as they move and only change their center positions. The lifetime of each object had mean value 50. Again the average number of objects per frame ranged between 500 and 2500.

We also generated a collection of datasets that was a mixture of the previous ones (the GN, or, generic collection), and consists of static objects, moving objects and objects that change extent over their lifetime. In particular, one third of the objects are static objects with the characteristics of the DG datasets. Another third are moving objects and the rest are objects that change position and extent, always linearly over the frame sequence. To generate some of the above datasets we used the GSTD generator [42]. In Table 1 we give the main characteristics of the datasets.

Table 1: The datasets used for testing the index structures.

Dataset	Avg Number of Objects per Frame	Total Number of Spatiotemporal Objects
DG	500, 1000, 1500, 2000, 2500	86807, 173925, 260933, 348006, 435056
MV	500, 1000, 1500, 2000, 2500	74017, 147996, 222096, 296012, 369858
GN	500, 1000, 1500, 2000, 2500	74346, 148597, 222970, 297272, 371598

It should be noted that to insert objects into a PPR-Tree, we first sort the dataset over the object insertion and deletion frames. Then the dataset is processed sequentially until the end of the evolution. For the 3D R-Tree the dataset is first sorted on the object insertion frames and objects are inserted in that order. For the Skeleton SR-Tree inserting the spatiotemporal objects according to insertion frame order tend to affect overlapping (since the ordering implies that an interval will probably overlap the next inserted interval). We got better performance when the spatiotemporal objects were inserted randomly.

Finally various query workloads were generated (separate workloads were created for range and nearest neighbor queries). A query workload consists of 1000 queries. A query is spatiotemporal in nature, i.e., it has a spatial and a temporal predicate. For the range queries, the spatial part contained 2D rectangles with three different sizes, Small, Medium and Large. The Small rectangles had lengths between 0 and 0.1, Medium between 0.1 and 0.3 and Large between 0.2 and 0.6. For the temporal predicate we distinguished between "snapshot" queries, where the temporal part was a single frame, and, "period" queries where each query specified a frame interval of length between 0 and 100. For the nearest neighbor queries the spatial part

was either a query point or a small rectangle uniformly inside the data space. The temporal part was a "period" selected randomly, with length between 0 and 100.

4.2 Tuning the PPR-Tree

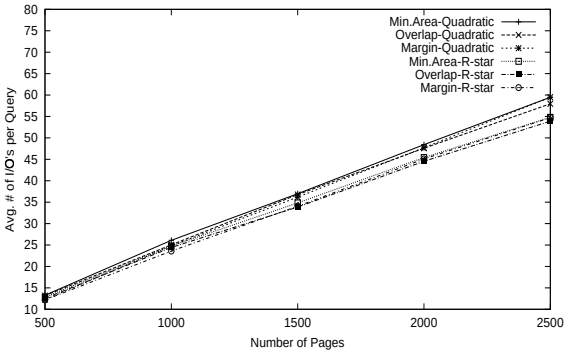

Figure 9: Query performance for snapshot queries and different merging/splitting policies.

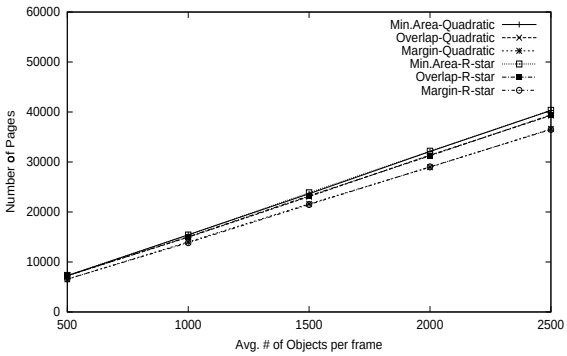

Figure 10: Space consumption for different merging/splitting policies.

A number of optimization issues have to be addressed when implementing the PPR-Tree. The most important of them are the merging and splitting policies. Note that the merging policies of the partially persistent B-tree are not applicable. The reason is that in a B-tree there is a single order among indexed objects; moreover, data is kept in pages according to this order. Consequently, for each underutilized page there are at most two possible sibling pages that it can merge with. On the other hand, a PPR-Tree stores multidimensional objects and for each page there are many possible sibling pages (all pages that have the same parent with the underutilized page are candidates). We used three merging policies. The first one, called *Overlap* chooses as a sibling the currently alive page that has the same parent and shares the most overlap with the underutilized page. The second one, (*Min_Area*), selects as sibling the page whose bounding rectangle area needs the least geometric expansion to incorporate the objects of the underutilized page. Finally, the third policy (*Margin*), finds the page that when merged with the underutilized page, has the least margin, which is the sum of the lengths of all sides of the bounding rectangle.

For the splitting policies, we use two methods. On is called *Quadratic* and it has been proposed in the original R-Tree paper. The other one (*R-star*) is the policy that is used by the R*-tree. The first policy assigns objects in two groups, initializing these groups by picking the pair of objects that would waste the most area if put in the same group. The R-star policy is based on determining various distributions of objects in a page, after ordering all objects in each dimension. The best distribution is selected, based on a set of criteria, such as minimizing the sum of margin values and also minimizing the overlap-area between the two generated pages.

In Figure 9 we plot the query performance (in average number of pages read per query) for all combinations of splitting and merging methods. We used the DG datasets and a snapshot query workload. As the figure shows, the query performance is mainly affected by the splitting policy (with the R-star policy providing better results than Quadratic). The merging policy has small effect. The space consumption of the PPR-Tree is depicted on Figure 10. Here the important factor is the merging policy and the Margin policy gives the best results. As a result, for the rest of our experiments we implemented the PPR-Tree using the R-star splitting policy and the Margin policy for merging nodes.

4.3 Degenerate Case

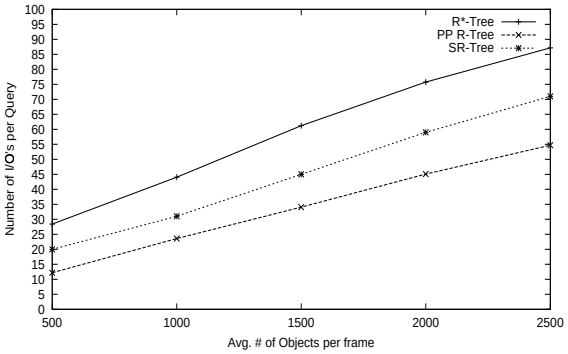

Figure 11: Query performance for small/ snapshot queries and DG datasets.

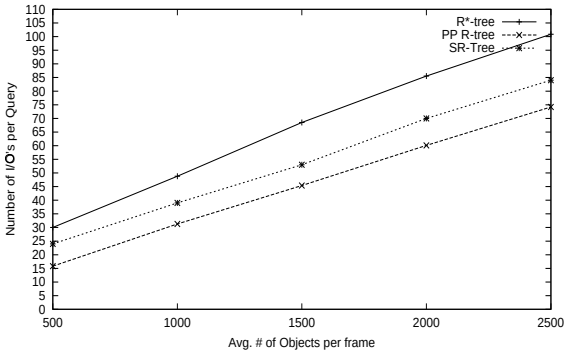

Figure 12: Query performance for medium/ snapshot queries and DG datasets.

We proceed with experimental results about the degenerate case. Since it contains objects with no position/extent changes it serves as a reference point for our later experiments. Figures 11-13 report the results for snapshot queries with Small, Medium and Large size (in spatial extent) respectively. The average lifetime of the objects is about 50 frames. In all cases the partially persistence methodology outperforms the Skeleton SR-Tree and the 3D R-Tree. The difference is higher for smaller queries. The SR-Tree behaves better than the R-tree since by placing spatiotemporal objects with long lifetimes higher in the tree it reduces overlapping. It should be noted that in our SR-Tree implementation, the experiments with average number of objects/frame equal to 2000 and 2500, produced comparatively very large number of overflow pages. Since these pages were not counted for the query I/O's, the depicted performance corresponds to interpolation from the behavior of the method for the 500, 1000 and 1500 experiments.

Figure 14 shows the results for Small/period queries. Here the query frame period ranged from 0 to 100, using a dataset with 1000 objects/frame. Interestingly, the R-Tree behaves better than the SR-Tree for period queries. This is due to object fragmentation. The larger the query period, the more copies of objects it will overlap with. The PPR-Tree's performance

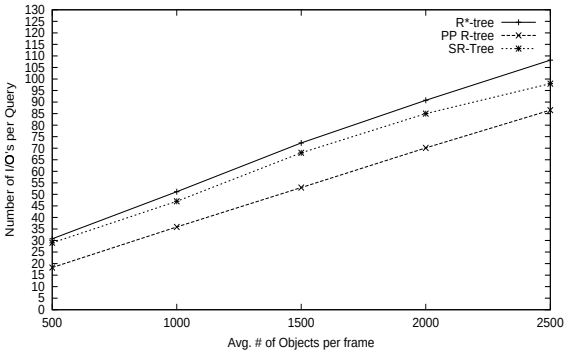

Figure 13: Query performance for large/ snapshot queries and DG dataset.

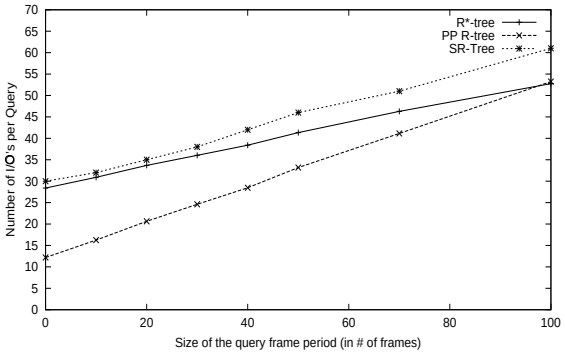

Figure 14: Query performance for frame period queries and DG dataset.

is also affected by the query period size. Since partial persistence is optimized towards frame queries, a query involving a large period (many subsequent frames) will overlap with many object copies thus decreasing query performance.

Figure 15 depicts the space consumption of both methods, for DG datasets. As expected the space consumption of the PPR-Tree is higher than the SR-Tree and the 3D R-Tree. Note though that the space overhead remains linear to the number of objects and it is about 2.5 times more than the space used by the 3D R-Tree.

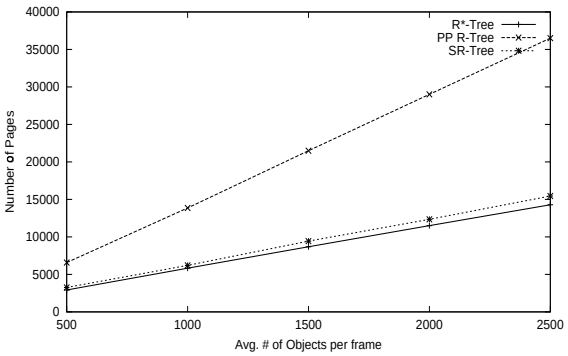

Figure 15: Space consumption for DG datasets.

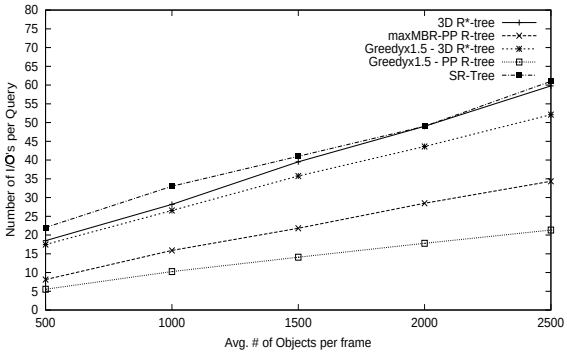

Figure 16: Query performance for small/ snapshot queries and MV datasets.

4.4 General Case

First we present our results for the moving rectangles datasets (MV) and then for the general datasets (GN). Given a dataset, the GREEDY algorithm derives first all spatiotemporal objects that yield the best gains in terms of empty space when split. Then these objects

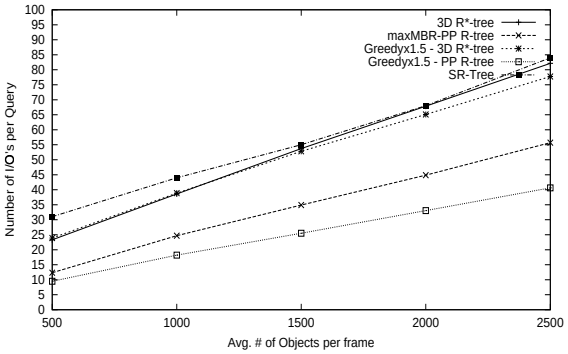

Figure 17: Query performance for medium/ snapshot queries and MV datasets.

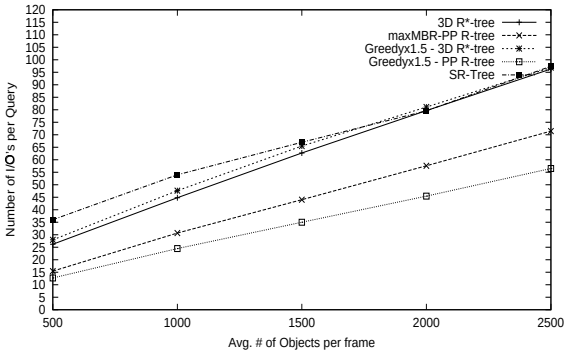

Figure 18: Query performance for large/ snapshot queries and MV datasets.

are split and the MBRs of the newly generated spatiotemporal objects are computed. Subsequently these MBRs are indexed by the PPR-Tree (marked as Greedy-PPR-Tree in the figures). To validate the expectation that a 3D R-Tree will not gain much by the artificial splits of the GREEDY algorithm, we indexed the resulting MBRs with a 3D R-tree, too (Greedy-3D R-Tree). We compare the two GREEDY approaches against the simple approach where no artificial split is considered. That is, we used a 3-dimensional MBR around each spatiotemporal object and indexed them using (i) a plain 3D R-tree and (ii) a Skeleton SR-Tree. Finally, we also used the $maxMBR$ approach for the PPR-Tree (maxMBR-PPR-Tree). Unless otherwise stated, the number of artificial splits were about half of the number of original spatiotemporal objects ($1.5N$).

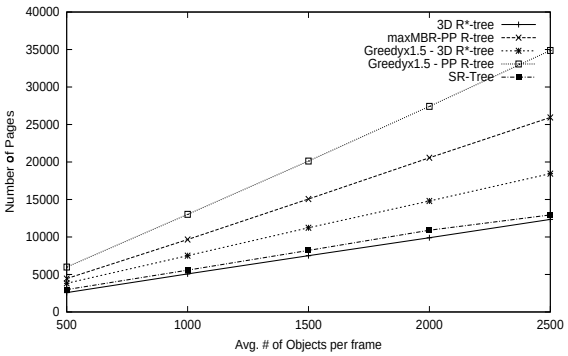

Figure 19: Space consumption for MV datasets.

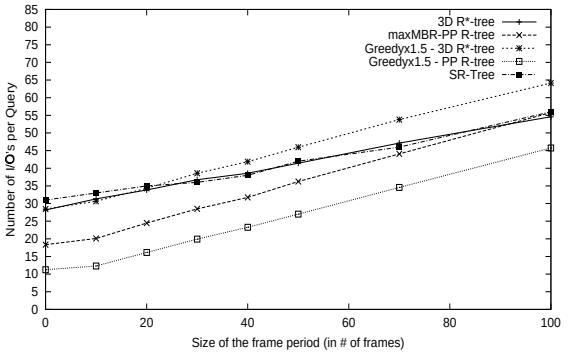

Figure 20: Query performance for frame period queries and MV datasets.

Figures 16-18 depict the results for snapshot queries and MV datasets. The greedy algorithm combined with the PPR-Tree provides the best query performance. Next is the simple PPR-Tree with the maxMBR approach. It is interesting to note that the 3D R-Tree performs

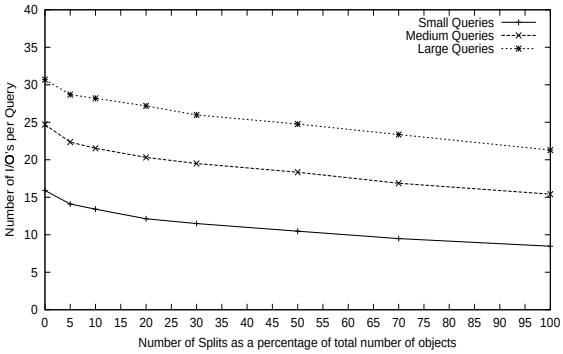

Figure 21: Query performance of the Greedy-PPR-tree for snapshot queries and different number of splits and MV datasets.

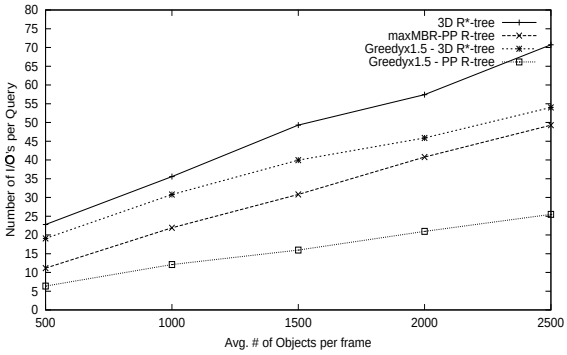

Figure 22: Query performance for small/ snapshot queries and GN datasets.

similarly with splits or no splits (i.e., as expected, the greedy splits do not provide a large advantage). A split may decrease the empty space but it increases the number of objects, affecting the 3D R-Tree query performance. The Skeleton SR-Tree behaves worse that the 3D R-Tree for the MV datasets. Since objects move, the corresponding MBR is rather large, not only on the frame dimension, but on the X and Y dimensions as well. The SR-Tree clustering based on the lifetimes is not so efficient anymore, and the method tends to perform like a regular R-Tree. The space for a method that uses the greedy approach is about 1.5 times the space of the same non-greedy method (Figure 19). Frame period queries appear in Figure 20 using a dataset with 1000 objects per frame. The Greedy-PPR-Tree method remains better than the other methods even for the larger periods we tried. It is also clear that as the query period increases, the performance of the greedy 3D R-Tree deteriorates against the 3D R-tree. This is because the splits introduced by the greedy approach introduce copies that the R-tree considers as separate objects. Finally, the SR-Tree behaves again very similar to the 3D R-Tree. For brevity of presentation, in the rest of our experiments the SR-Tree is omitted.

The effect of using different number of splits is examined in Figure 21. The query performance is shown for three MV snapshot query workloads with 1000 objects per frame and different number of splits. For brevity only the Greedy-PPR-Tree is presented. The dataset it was a MV dataset with 1000 objects per frame. Clearly increasing the number of splits improves the query performance. The space is also increasing proportionally to the split percentage increase (and is thus not depicted).

The performance comparisons for the general datasets (that include mixtures of moving/static/extending objects) appear in Figures 22 to 27. All methods behave very similar to the results for the moving objects datasets. Despite using the greedy algorithm as an approximation for the extending objects, the Greedy-PPR-Tree still provides the best performance.

The performance for nearest neighbor queries is similar to the range queries. For brevity, we report results for the general datasets (GN), but the same trend was observed for the other

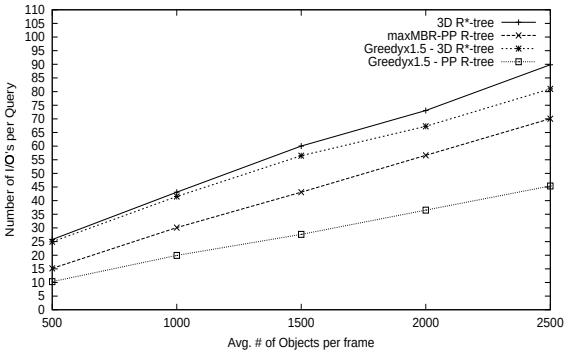

Figure 23: Query performance for medium/ snapshot queries and GN datasets.

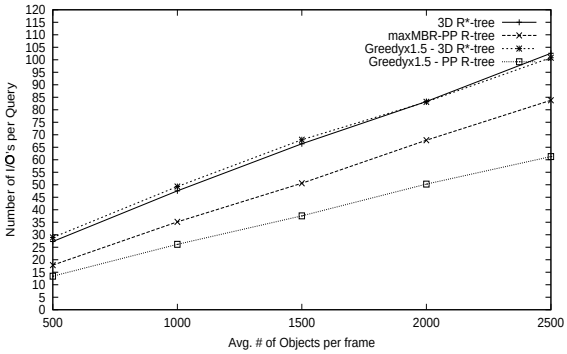

Figure 24: Query performance for large/ snapshot queries and GN datasets.

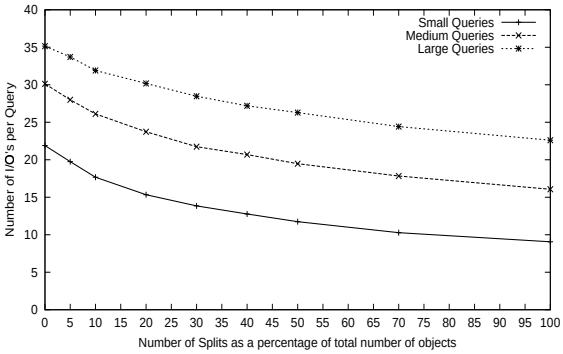

Figure 25: Query performance of the Greedy-PPR-Tree for snapshot queries and different number of splits and GN datasets.

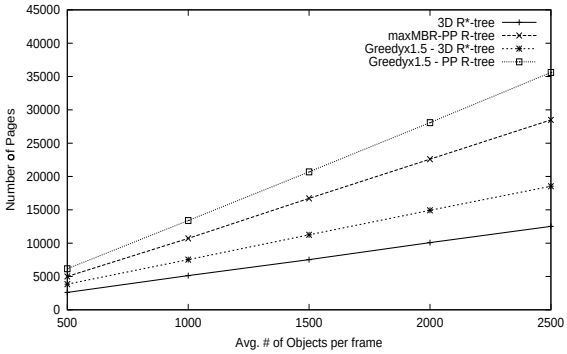

Figure 26: Space consumption for the GN datasets.

datasets as well. In Figure 28 the average query performance is shown for a set of 50-Nearest Neighbor queries (that is, find the 50 nearest objects to the query object). The frame period was 20 frames. Figure 29 reports results for nearest neighbor queries with different frame periods. The Greedy-PPR-tree has again the best query performance.

Finally, in Figures 30 and 31 we present the total number of I/O's needed to create each of the index structures. Here, we assume a cache of only 10 pages. Using larger the construction time can be decreased considerably. The 3D R-Trees have lower construction time that the PPR-Trees. This is not surprising. Clearly, for the partially persistent methods the index is accessed twice for each spatiotemporal object: once at the insertion frame and again at the deletion frame. On the other hand for the 3D R-Trees, the index is accessed only when the MBR of the spatiotemporal object is inserted. However, for the Off-line problem, the index is created only once and then is used for the querying, i.e., the update cost is not that critical.

5 Related Work

Although recently there has been extensive work on multimedia and video databases, the approach discussed in this paper is novel. The work in [45] considers only static objects (degenerate case) and uses a 3D R-Tree approach to index the objects. Another work that proposes indexing video objects in order to answer mostly temporal queries appears in [1]. In this, video movies are preprocessed and all entities of interest such as objects, activities, and events, are identified. Subsequently, these entities are associated with specific frames in which they appear. Therefore, every entity is coupled with a set of frames which can be viewed as a set of line segments (if consecutive frames are put in one line segments). A main-memory Segment Tree [34] is used to store the resulting line segments. Queries that this structure can answer are of the type: "find the objects that appear when a specific event happened" or "find the objects that appear in all frames where a specific object appears". Also the authors discuss how to store higher level information for each object in order to answer more complex queries. However, most of the complex queries have query time linear to the total number of video objects.

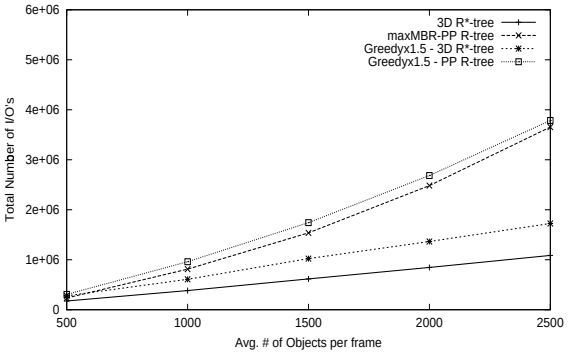

Figure 30: Construction cost for MV dataset.

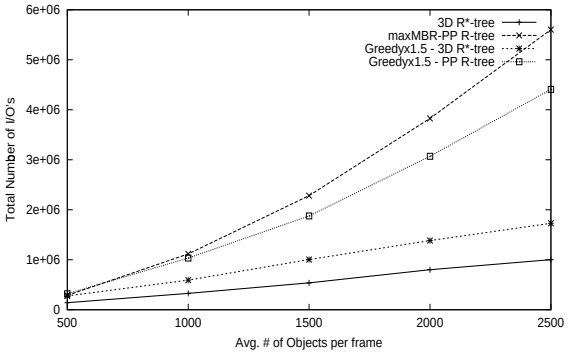

Figure 31: Construction cost for GN dataset.

Another interesting approach to index video data has been proposed in [8, 9]. There video data is indexed using not only information about the color or texture (as in image databases) but also motion and spatiotemporal information. First a video movie is partitioned into shots or scenes. Then all objects that appear inside each shot (called video objects) are found. For each object information about its features (color, texture and shape), but also about its motion is stored. In particular, the motion of an object is stored as a trail of the object position from one frame to another. The user can ask queries using a visual interface, and can give different weights for each feature. In [39], algorithms to index these video objects are presented. Each object is mapped to a high dimensional space which is then split into a few low dimensional feature vectors. Querying is performed for each vector separately. Yet another work that represents the motion of an object by using its trail is [12]. Our approach is complementary to these works and can thus be used to enhance the query capabilities of the aforementioned systems.

Content-based retrieval has also been an active research area in the past few years and several systems have been developed. These systems allow image indexing by using low-level image features such as color histograms, texture and shape. The user specifies a target image (QBE) or a sketch and the system retrieves the most similar images to the target image. Some examples of very successful systems in these area include QBIC [15], Virage [17] and VisualSEEk [36]. However, all these systems support retrieval of still images. Some of these ideas has been used to index movie databases by using low level features combined with some semantic information [37][8].

Related is also research in the area of spatiotemporal database indexing. In particular, [41] summarizes the issues that a spatiotemporal index needs to address. In an early paper [47], the RT-tree is presented, an R-Tree that incorporates time into its nodes. Each object has a spatial and a temporal extent. For an object that is entered at time t_i the temporal extent is initialized to $[t_i, t_i)$. This temporal extent is updated (increased) at every time instant that this spatial extent remains unchanged. If the spatial extent changes at time t_j, a new record is created for this object with a new temporal extent $[t_i, t_j)$. Clearly, this method is

inefficient due to its large update overhead. In [27, 44, 47, 28] the idea of overlapping trees is used to make an index partially persistent. Different indices are created for each time instant, but to save space, common paths are maintained only once since they are shared among the structure. However the overlapping method has a logarithmic space overhead, since every time an update is made, the whole path from the root to the updated leaf node has to be copied. Indeed, in an experimental evaluation presented in [28] the overlapping R-Tree (HR-Tree) has an order of magnitude higher space overhead that the 3D R-Tree. It should be noted that the GREEDY algorithm presented in this paper is general and can be used to enhance the performance of any partially persistent method (including the overlapping approach). In another recent work [31], an R-Tree is extended to support transaction and valid time. However, this work concentrates on the combination of degenerate evolutions and bitemporal datasets. Spatiotemporal indexing as examined here deals with historical queries about the spatiotemporal evolutions. Work dealing with future queries about the position of moving objects (assuming knowledge of movement functions) appears in [32][22][2].

6 Conclusions and Further Research

We have examined the problem of indexing objects in animated movies. We proposed to represent a movie as a spatiotemporal evolution and reduce the original problem to a problem of partial persistence. However, the partial persistence approach considers only objects that remain unchanged during their evolution (i.e., between the frames they appear). This is not realistic in animated movies where objects can change their extent/position among frames. We presented an efficient way to represent such complex objects. In particular, we formulated this problem as an optimization problem and provided an optimal greedy algorithm for the case of linearly moving objects. Our solution is also optimal for objects that change linearly only one of their extent dimensions. However, it is suboptimal for objects that change both their extent dimensions. The presented approach provides very fast query time at the expense of some extra space, which however is linear to the number of changes in the frame evolution. We have shown the merit of our method by comparing it with an approach that sees the frame sequence as simply another dimension and uses (i) a regular 3D R-Tree, or, (ii) a Skeleton Segment R-Tree.

An interesting future direction is to consider objects that change position and/or extent with non-linear functions. Clearly, for this case, the monotonicity property does not hold. We are examining the existence of efficient algorithms that approximate the optimal solution with a good approximation ratio.

Another problem that we plan to investigate is the case of On-Line indexing. This paper considered only the Off-Line case, where all objects and their evolution is known beforehand. However, in many real life applications, objects are inserted in an on-line fashion in the dataset. We expect that an on-line version of the optimal greedy algorithm will give a good approximation of the optimal solution.

Yet another interesting avenue of research is to extend the techniques presented here

to different query scenarios. This includes queries where the view point changes in time. One application we can consider is the following: assume that the original two-dimensional model that we use to build an animated movie extends further than the screen, and that the actual animated movie that we see is in fact a specific cut. The cut (that is, the visible part of the movie) depends on where we position the screen window. Assuming that this position remains constant, we can find all visible objects by answering a three-dimensional range query. That is, a two-dimensional range query in the visible screen is translated into a three-dimensional spatiotemporal query. If however the position of the screen does not remain constant, the shape of the spatiotemporal query becomes more complicated. Consider for example answering range queries while the screen zooms in or out. Assuming that the size of the range query on the screen remains constant relative to the size of the screen, if we are zooming-in objects will appear larger and fewer objects will be in the query area. This query can be mapped to a spatiotemporal query that looks like a pyramid. We can approximate this query by a number of spatiotemporal range queries using the same technique that we use to optimally bound a moving object with minimum bounding rectangles. When zooming, the viewpoint changes location along an axis perpendicular to the frame plane. A more involved problem is answering such range queries when the viewpoint is translated as well as moving closer or further from the frame, or, if we consider three-dimensional objects, when the view point moves and rotates in space.

Finally, we note that our approach is general and can be applied to other spatiotemporal applications as well (for example indexing forest extends or city boundaries over time, etc.).

7 Acknowledgement

This research has been supported by NSF grants IIS-9509527, IIS-9907477 and by the Department of Defense. The authors would like to thank Elias Koutsoupias for many helpful discussions and Bernhard Seeger for providing us with the R*-tree code. (An early version of this paper was presented in the International MIS Symposium, MIS '99).
